Received: April 2012 Accepted: June 2012

Abstract

In the present study, different oxygen levels were examined in two weight groups of great sturgeon *Huso huso* including small size (with initial weight 280.9 ± 49.2 g) and large size (with initial weight 1217.9 ± 138.1 g). The fish were kept in hypoxia (2-3 mg/l), normoxia (5-6 mg/l) and hyperoxia (9-10 mg/l) conditions for 8 weeks and then were individually placed in the tanks with oxygen level of 6 mg/l to levels causing sedate fish and subsequently dissolved oxygen level in water was measured every 30 minutes. No significant effects on blood cortisol and glucose levels were observed after 8 weeks ($P > 0.05$), but there were significant differences in cortisol concentrations between treatments ($P < 0.05$) after stress. Significant differences were found in cortisol and glucose levels in pre and post stress conditions in small size, but no significant differences were observed ($P > 0.05$) in large size. There were no significant differences in oxygen consumption among treatments ($P > 0.05$). Results revealed that dissolved oxygen had a significant effect on growth of *H. huso* and also a low level of oxygen accompanied by reduction in feed intake resulted in lower growth and changes in stress response.

Keywords: *Huso huso*, Growth performance, Hypoxia, Hyperoxia, Oxygen consumption

Introduction

The dissolved oxygen (DO) level plays a key role in water quality in aquaculture (Timmons et al., 2001; Valverde et al., 2006) and adequate concentrations of oxygen in water are vital to intensive fish farming (Ritola et al., 2002). The measurement of oxygen consumption is an indirect way to estimate metabolism in fish (Pichavant et al., 2001). DO, besides feed and temperature, is the most important factor controlling growth, and a constant DO content below a critical level is considered to decrease feed consumption, growth and feed conversion efficiency (Jobling, 1994). Critical range of oxygen for acceptable growth is about 5 mg/l (Brett, 1979) and for feed intake is about 50-70% saturation (Jobling, 1995). Boyd (1982) demonstrated that DO concentration between 3-5 mg/l is harmful for fish growth.

In intensive aquaculture of many species, it is now common to oxygenate the water to increase biomass and production (Olsvik et al., 2006). Exposure to both hyperoxia and hypoxia may damage to aquatic organisms, resulting in suboptimal growth and hence lower biomass production (Wedemeyer, 1997), but long-term effects of exposure to hyperoxia are less known (Olsvik et al., 2006).

Stress is a situation in which the organism's homeostasis is threatened by endogenous or exogenous stimuli, whereas the stress response is the adaptive strategy enabling individuals to cope with the situation (Chrousos and Gold, 1992). Handling, transport, confinement, social hierarchies, agonistic behavior, poor water

quality (e.g. hypoxia) and xenobiotics are conditions causing stress responses in aquaculture (Barton and Iwama, 1991; Davis, 2006). Studies on various fish species and different types of stressors have led to the conclusion that behavioral and physiological responses to stressors are vary between species and type of stressor (Barton and Iwama, 1991; Iwama et al., 2006).

The primary indicator of stress response is the increase of serum cortisol level (Cataldi et al., 1998) and it is most commonly measured indicator of stress that usually provides a good reflection of the severity and duration of the stress response (Barton and Iwama, 1991; Wendelaar Bonga, 1997; Fevolden et al., 2002).

The sturgeons are the members of chondrosteans that most species are worldwide endangered because of overfishing, pollution and habitat degradation (Birstein, 1993; Billard and Lecointre, 2001). Thus there has been an increased demand for information on all aspect of sturgeon biology and physiology (Billard and Lecointre, 2001; Baker et al., 2005) find the knowledge in aquaculture or stocks rehabilitation of these species.

Great sturgeon or beluga (*Huso huso*) is the largest sturgeon and it is suitable for aquaculture because of fast growth, reproduction in captivity, and tolerance of unfavorable rearing conditions (Vlasenko, 1994; Falahatkar et al., 2009), reared as fingerlings in some Iranian government hatcheries for stocks enhancement, but are also selected for culture in confined systems for commercial purposes (Falahatkar et al.,

2009). Stressors such as grading, handling, crowding and poor water quality can have deleterious effects on growth and welfare of *H. huso* (Falahatkar et al., 2009). Results of Falahatkar and Barton (2007); Rafatnezhad et al. (2008) and Falahatkar et al. (2009) suggest that *H. huso* is relatively resistant to handling disturbances during aquaculture practices, but are nevertheless responsive to stress factors. Despite the economic importance of *H. huso* there is little information about the oxygen requirements of this species, thus the objective of this study was conducted to determine the biochemical factors in blood including serum cortisol (as primary response) and glucose (as secondary response) levels, growth performance and oxygen consumption in two weight group of *H. huso* that reared in water with three different saturation levels of DO ; hypoxia, normoxia, and hyperoxia then exposed to low oxygen stress.

Materials and methods

Fish

Twenty seven fish with mean initial body weight of 1217.9 ± 138.1 g (as large size)

and 54 fish with mean initial body weight of 280.9 ± 49.2 g (as small size) were provided from International Sturgeon Research Institute (Rasht, north of Iran).

Experimental design

The fish were held in 18 fiberglass tanks (1 m diameter with water depth 30 cm, 0.8 m² surface area and 500 L volume) at a water temperature of 18 ± 0.7 °C, NO₂ 0.02 ± 0.01 mg/l, Fe 0.025 ± 0.001 ppm, NH₄ 0.00 and pH= 6.4 under controlled photoperiod (18L:6D) during the experimental period. Fish were acclimated to experimental tank for one week then randomly distributed in 9 tanks for each weight group (3 fish per tank in large size (3653.7 ± 322.1 g) and 6 fish per tank for small size (1685.3 ± 55.3 g). Food was offered three times (8:00, 16:00, 24:00) daily with a dry diet made at International Sturgeon Research Institute for this species (44.8 % crude protein; 18.9 % crude fat; 10.28 % ash; 1.17 % fibre)(Table 1). Food was supplied as 1–2 % body weight daily, according to water temperature during the experimental period.

Dissolved oxygen was measured by an oxymeter (OXi323-B/SET) 6 times a day (8, 11, 13, 16, 20, 24). Oxygen treatments including hypoxia (2-3 mg/l), normoxia (5-6 mg/l) and hyperoxia (9-10 mg/l) (Brett, 1979; Boyd, 1982; Jobling, 1995; Buentello et al., 2000; Crampton et al., 2003) were set up with managing inflowing water and using system equipped with oxygen enriching for hyper oxygenation (pure oxygen injected). Hypoxic conditions were obtained by reducing the water inflow (without reducing water volume in the tank) and reducing aeration in the tanks. Oxygen content gradually decreased to 2-3 mg/l. The inflowing water in all treatments was

the same as that of hypoxia. In normoxia treatment the oxygen saturation set up with aeration system. Fish were kept in this situation for 8 weeks.

Sampling and analysis

Biometric measurements of fish were carried out every 2 weeks. To obtain blood samples, 1 fish per tank from large size and 2 fish from small size were taken. After initially sampling of all 27 fish (9 fish in large size and 18 in lower weight), aeration and water flow were stopped. After sedation, blood samples were taken again from the same 27 fish. Approximately, 2 ml of blood were taken from the caudal vein of each fish using a 5

ml syringe (Hrubec and Smith, 2000). Test tubes containing blood were centrifuged for 10 min at 3000 g. Serum was stored at -20°C for measuring cortisol and glucose levels. Serum cortisol was measured by radioimmunoassay (Redding et al., 1984), and glucose was measured using glucose oxidase methods (Bayunova et al., 2002). Oxygen consumption was measured according to the following formula (Valverde et al., 2006):

$$\text{MO}_2 = \frac{([\text{O}_2]_{t1} - [\text{O}_2]_{t2}) \times V}{(B \times t)}$$

where MO_2 is the individual oxygen consumption expressed as $\text{mg O}_2/\text{kg/h}$; $[\text{O}_2]_{t1} - [\text{O}_2]_{t2}$ is the difference in oxygen concentrations ($\text{mg O}_2/\text{l}$) over measurement time; V is the volume of the tank in liter; B is fish biomass in kg , and t is time (h) during which oxygen consumption was measured. The tanks filled with water and covered with a plastic sheet to prevent diffusing atmospheric oxygen and then the groups were placed in different tanks according to their size (30 l for small size and 90 l for larger one). Fish were placed individually in the tanks and from oxygen saturation 6 mg/l to the fish sedation, every 30 min O_2 concentration in water was measured using an oxygen-meter.

Statistical analysis

At first, Kolmogorov-Smirnov test was applied to check the data normality. Data

collected from the experiment were subjected to One-Way analysis of variance (ANOVA) test using SPSS 13.0 (Chicago, IL). When a significant difference was found, the differences between treatment means were determined by Tukey's tests as a post-hoc test. Effects of fish weight as a covariate on glucose and cortisol determined by ANCOVA analysis and there were no significant difference then student's t-test were done to determine differences between pre-stress and post-stress group means. Differences were considered statistically significant when $P < 0.05$. Data are expressed as mean \pm SE for each treatment.

Results

No mortality was observed over the eight weeks of the experimental period. Oxygen levels influenced growth parameters of *H. huso*. Mean weight of the fish were unaffected by oxygen treatments for the first 4 weeks in small size and for the first 2 weeks in large size, but after that until the end of the study, fish showed significant differences in mean weight ($P = 0.005$, Fig. 1). In small size, oxygen treatments showed significant differences in fork length ($P = 0.019$, Table 2). There were significant differences in feed intake between treatments in both groups ($P = 0.019$, Table 2).

Figure.1: Mean weight of *H. huso* during 8 weeks rearing under different oxygen levels.A: small size. B: large size. Significant difference were shown by different letter (a, ab, b) as determined by ANOVA and Tukey's test at $P \leq 0.05$. All values are mean \pm SE.

Table 2: Growth parameters of *Huso huso* after 8 weeks rearing under different oxygen levels.

Group size	Oxygen level	Initial weight (g)	Final weight (g)	Initial fork length (cm)	Final fork length (cm)	Feed intake (g)	CF	SGR (%day ⁻¹)	Survival rate (%)
Small	Hypoxia	282.9±12.8	396.8±14.7 ^b	35.2±0.5	40.2±0.6 ^b	167.4±1.7 ^b	0.61±0.02	0.61±0.05 ^b	100
	Normoxia	276.9±11.6	490.6±28.4 ^a	35.9±0.5	42.6±0.8 ^a	249.0±3.1 ^a	0.60±0.05	0.99±0.06 ^a	100
	Hyperoxia	282.9±11.0	522.0±23.3 ^a	36.0±0.4	42.2±0.4 ^{ab} _{***}	257.0±11.7 ^a	0.69±0.02	1.09±0.06 ^a	100
Large	Hypoxia	1177.2±43.1	1272.8±55.2 ^b	55.7±0.8	58.8±0.7	211.4±14.8 ^c	0.62±0.03 ^b	0.14±0.14 ^c	100
	Normoxia	1194.7±51.4	1420.2±67.2 ^b	56.2±0.9	59.9±1.0	565.2±2.0 ^b	0.66±0.01 ^b	0.31±0.13 ^b	100
	Hyperoxia	1292.9±4.0	1721.4±75.8 ^a	56.1±0.7	58.2±1.5	734.6±48.5 ^a	0.84±0.08 ^a	0.50±0.05 ^a	100

Significant differences among different treatments were shown by a different superscript in the columns (a, ab, b and c) at $P \leq 0.05$. Significant differences were determined by ANOVA and Tukey's test for each parameter. All values are mean \pm SE.

The effects of hypoxia, normoxia and hyperoxia showed no significant effect on cortisol and glucose levels after eight weeks in large size ($P = 0.926$ and 0.531 , respectively) and small size ($P = 0.308$ for cortisol and $P = 0.433$ for glucose), but after stress there were significant differences in cortisol concentrations between treatments in small size ($P = 0.001$) and large size ($P = 0.012$). There were no significant differences in glucose levels between treatments in small size ($P = 0.655$) and large size ($P = 0.776$). Significant differences between cortisol values before and after stress in small and large size ($P = 0.006$ and 0.001) and glucose levels in small size were found

($P = 0.002$) but in large size, no significant differences in amount of glucose were observed ($P = 0.874$; Figs. 2, 3).

There were no significant differences between oxygen consumption in treatments in large size ($P = 0.889$) and small size ($P = 0.864$; Fig. 4). The lowest amount of oxygen that fish could stand at normoxia and hyperoxia treatments was 0.88 mg/l in small size and 0.94 for normoxia and 1.07 for hyperoxia in large size. The O_2 content that fish in hypoxia treatment could resist in large size was 0.71 mg/l but in small size fish could stand even until the amounts of O_2 in water was 0.57 mg/l.

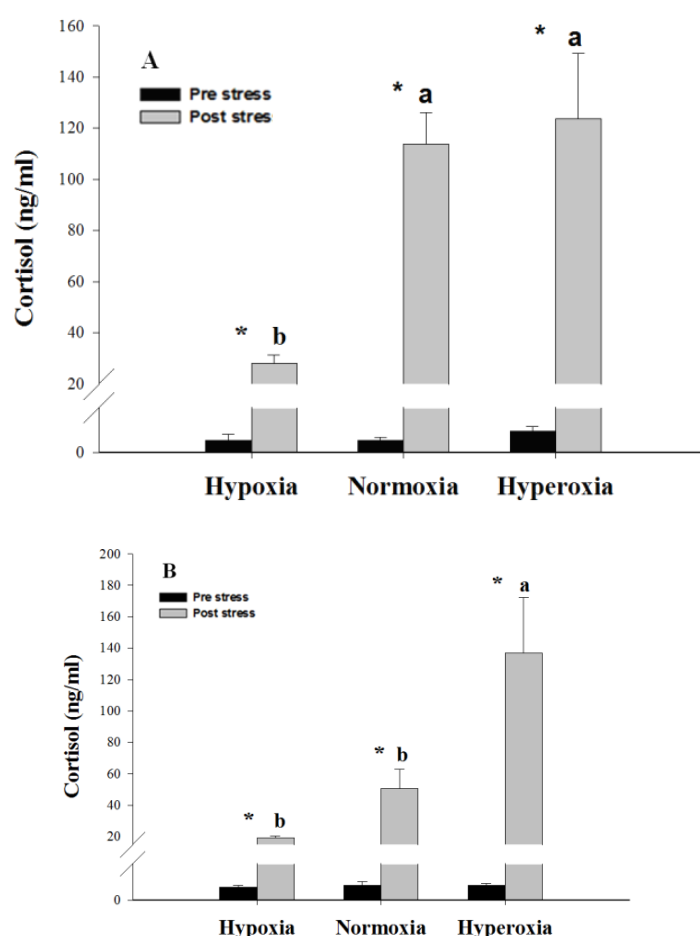

Figure 2: Serum cortisol levels (mean \pm SE) pre and post oxygen deprivation stress of *H. huso* that reared at different oxygen levels for 8 weeks. A: small size (n=18). B: large size (n=9). Significant

differences among different treatments were shown by a different superscript in the columns (a, b) at $P \leq 0.05$ as determined by One Way ANOVA and Tukey's test. (*) shows significantly different ($P < 0.05$) as determined by Student's t-test between pre stress and post stress

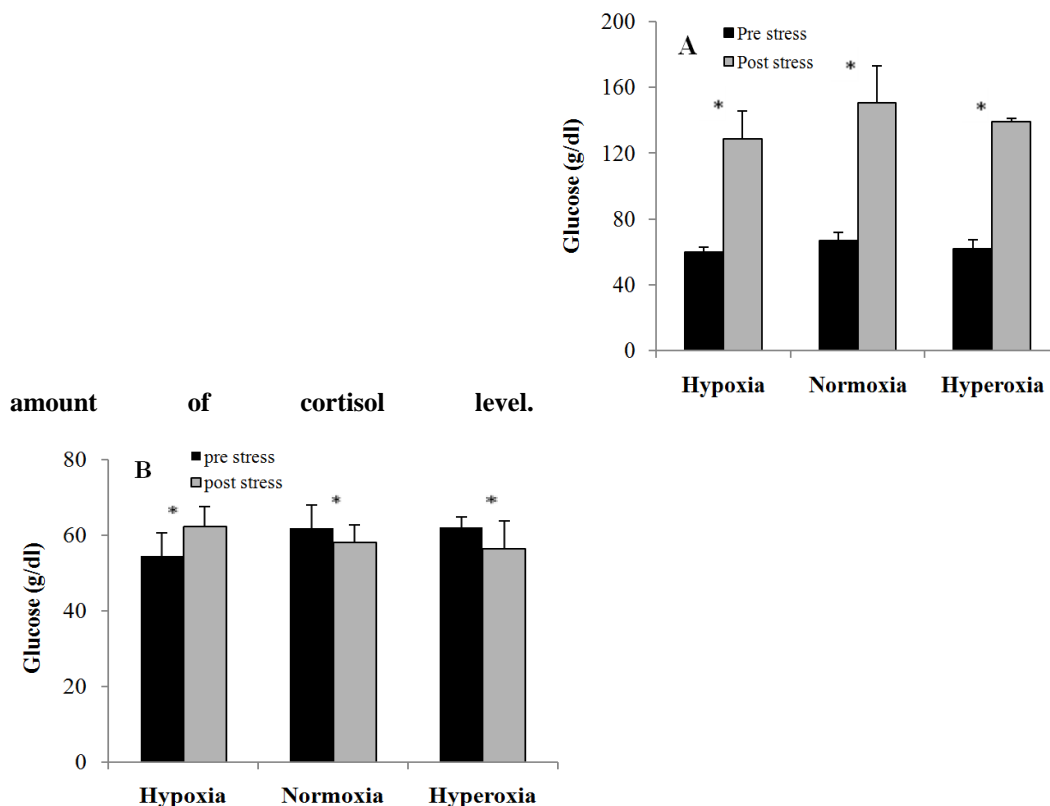

Figure 3: Serum glucose levels (mean \pm SE) pre and post oxygen deprivation stress of *H. huso* that reared at different oxygen levels for 8 weeks. A: small size (n=18). B: large size (n=9). * shows significantly different ($P < 0.05$) as determined by student's t-test between pre stress and post stress.

Discussion

Growth

At the end of the experiment, in large size the mean body weight of fish reared at hyperoxia treatment was significantly higher than in the group maintained at hypoxia and normoxia treatment. Similarly, the growth of halibut (*Hippoglossus hippoglossus* L.) progressively increased when the oxygen saturation increased from 57 to 100% (Thorarensen et al., 2010). There is some evidence that moderate hyperoxia may improve the growth of fish (Foss et al., 2003; Dabrowski et al., 2004; Hosfeld et al., 2008) while Person-Le Ruyet et al. (2002) reported that after exposure to O₂-supersaturation for 30 days juvenile turbot (*Scophthalmus maximus*)

showed no significant differences in feed intake and growth. In the other study, Ritola et al. (2002) stated that none of episodic hyperoxia treatment or continuous hyperoxia caused mortality or result in better growth in rainbow trout (*Oncorhynchus mykiss*). The results of the present study concur with those of several other studies, which indicate that oxygen saturation close to 100% or even higher required to support the maximum growth (Buentello et al., 2000; Crampton et al., 2003). In the present study growth of the fish reared at hypoxia treatment was significantly lower than normoxia and hyperoxia in small size. Tran-Duy et al. (2008) stated reduced feed intake and growth of Nile tilapia (*Oreochromis*

niloticus) with an average weight of 37 and 190 g at DO concentrations of about 2.8 mg/l and 3.2 mg/l. Feed intake and satiation in fish are regulated by physiological, social or environmental factors, or by the interaction among them (Tran-Duy et al., 2008). Rafatnezhad and Falahatkar (2011) mentioned that the most important factors responsible for the differences in growth are primarily oxygen concentration. So, decrease in oxygen content could regulate the growth of *H. huso* juveniles. The results from present study clearly showed reduced feed intake and growth of *H. huso* at hypoxic condition. Fish stop eating when oxygen supply does not satisfy oxygen demand (Pauly, 1981). Decreased feed utilization might be an indicator of the higher levels of stress (Rafatnezhad and Falahatkar, 2011) and it could be an indirect mechanism by which prolonged hypoxia reduces growth and may be a way to reduce energy and thus oxygen demand (Pichavant et al., 2001).

Oxygen consumption

In the present study there were no significant differences between oxygen consumption in treatments in large size and small size. Considering that the time course and severity of hypoxia greatly influence the degree of physiological responses of fish (Boutilier et al., 1988). Randall (1982) described that fish respond to a decrease in the levels of dissolved oxygen by increasing both ventilatory frequency and ventilation volume rate. The cost for ventilation has been estimated at the level of 3–10% of the resting oxygen consumption at normoxia (Farrell and Steffensen, 1987; Rantin et al., 1992), but it

may increase to 50% at hypoxia (Hughes and Saunders, 1970). So, any increase in ventilation will reduce the energy available for other metabolic processes such as growth (Jones, 1971). During hypoxia, increased pumping will induce a rise in oxygen demand (Berschick et al., 1987). With declining oxygen tensions a point is reached, the critical oxygen tension, at which the oxygen demand of the respiratory pumps exceeds the extra oxygen supplied by hyperventilation and so oxygen consumption declines (Hughes, 1973). In the present study, there were no significant differences between oxygen consumption in the treatments but in hypoxia, fish could resist at low oxygen concentration more than other treatments. This can be related to changes in respiratory mechanism of fish in hypoxia treatment during 8 weeks of experiment. Oxygen consumption rate varies with fish weight and maximum oxygen uptake capacity relative to body weight in bigger fish is lower than in smaller one, because the gill surface area is allometrically related to body weight (Tran-Duy et al., 2008). Similarly, in the present study fish in large size had smaller oxygen uptake. Foss et al. (2003) reported that in spotted wolffish (*Anarhichas minor*) O₂ consumption was significantly higher under hyperoxic compare to normoxic conditions. Thillart and Verbeek (1991) reported excess oxygen consumption in goldfish, *Carrasius auratus*, after varying durations of hypoxia and anoxia.

Some species of sturgeon exhibit significant reductions in routine metabolic rates when exposed to hypoxia (Ruer et al.,

1987; Crocker and Cech, 1997) but Nonnotte et al. (1993) demonstrated that Siberian sturgeon, *Acipenser baeri*, exhibited a doubling in the respiration rate after returning to normoxia from a progressive hypoxic exposure over 4.5 h when compared to a normoxic control. They have shown that sturgeon, like most other fish, exhibit typical O₂ regulatory behavior when subjected to gradual and moderate hypoxia.

Stress responses

There was no significant difference in glucose and cortisol levels between the treatments at the end of the experiment. Reasons for the apparent low responses to stressor in *H. huso* may be related to their evolutionary history associated with the development of their adaptive responses to stressors in their natural environment (Falahakar and Baron, 2007). Barton and Iwama (1991) mentioned that cortisol levels around 10 ng ml⁻¹ is a level generally considered representative of unstressed fish, thus the slow and relatively weak cortisol response to stressors, and low serum glucose levels at the end of experiment may be related to the adaptation of *H. huso* to experimental treatments after 8 weeks.

After stress, there were no significant differences in glucose levels between the treatments but in small size there was significant difference before and after stress. After stress, there were significant differences in cortisol levels between the treatments in both groups. In small size in hyperoxia average of cortisol concentration significantly elevated but in hypoxia fish showed lower amount of cortisol and average of cortisol

concentration significantly changed. Average of cortisol concentration in fish from normoxia was within the amount of cortisol in hypoxia and hyperoxia treatment. In large size the increase of cortisol after stress was significant. This difference in responses to stress between hypoxia and hyperoxia treatments may be related to sturgeon ability to adapt effectively to low O₂-concentrations. This adaptation is attributable to several changes that may occur during long-term exposure to non-lethal hypoxia; increases in the oxygen-carrying capacity or increase in the tissue glycogen reserves (Jobling, 1994). In large size, higher level of cortisol in hyperoxia treatment may be related to 8 weeks rearing in high level of oxygen saturation in which the fish could not resist at lower amount of oxygen saturation during stress.

There are several reports about response of fish to stressors that are related to hypoxia. For example, high levels of catecholamines were observed by Metcalfe and Butler (1989) in *Scyliorhinus canicula* submitted to moderate hypoxia. Lays et al. (2009) reported that when spotted wolffish were exposed to a gradually decreasing oxygen level in the tank, a significant elevated plasma cortisol level (35 ng ml⁻¹) was seen in the fish that remained in the tank until oxygen saturation had decreased to 20% oxygen saturation after 2.5 h and plasma glucose levels showed only moderate increases (~70%) following disturbance and hypoxia challenges. In other study on turbot after an exposure to moderate hypoxia (45% of O₂-saturation) no sign of stress was noticed (Pichavant *et al.* 2000). In Sole, *Solea solea*, no major change in the physiological status was observed after a 12-

hour exposure to a hypoxic challenge of 40% O₂-saturation (Dalla Via et al., 1994; Thillart et al., 1994). Fridell et al. (2007) reported that after combination of hyperoxygenation and reduced water flow (hyperoxic) the cortisol levels were significantly higher in hyperoxic group compared to controls maintained under normal oxygen saturation and water flow (normoxic) indicating chronic stress. This is supported the result of present study that after stress, the fish placed in hyperoxia and normoxia treatment could not resist at that situation and significantly showed high levels of cortisol in both large and small sizes. In other study, Person-Le Ruyet et al. (2002) demonstrated that after exposure to O₂-supersaturation for 30 days, juvenile turbot showed no sign of stress. In summary, the results of present study revealed that weight groups had no effects on stress indices at the end of experimental period and this is according to previous studies with juvenile *H. huso* (Falahatkar and Barton, 2007; Rafatnezhad et al., 2008, Falahatkar et al., 2009), thus the findings suggest that this species is relatively resistant to stressors during aquaculture practices and fish did not show high levels of glucose and cortisol at the end of the experiment. This showed that *H. huso* could adapt to different oxygen conditions. Results of the present study revealed that dissolved oxygen had a significant effect on growth and a low level of oxygen accompanied by reduction in feed intake result in lower growth. More future studies about other related indices and gene expression can be useful.
